# Jeแाell Instruments <br> MAKING SENSE OUT OF MOTION 

## EFFECT OF CROSS-AXIS INCLINATION ON THE SCALE FACTOR OF 756-SERIES MID-RANGE MINIATURE TILT SENSORS

Tilt sensors are calibrated by tilting them in a vertical plane and measuring their outputs at known angles. If a sensor is subsequently inclined by the cross-axis angle $\beta$ (Figure 1) and again rotated in a vertical plane, its output at the same known angles will be different than in the initial calibration.

We evaluated the cross-axis performance of a Model 756-1172 Tilt Sensor by inclining and then calibrating it at cross-axis angles from $-20^{\circ}$ to $+20^{\circ}$. A signal conditioning module with analog voltage output (Jewell Instruments Model 84828) was used in the calibrations. In each test, we tilted the sensor in $0.5^{\circ}$ steps over its full range of $\pm 10^{\circ}$.

Calibration of this sensor yielded an obvious cosine relationship between the scale factor and the cross-axis inclination (Figure 2). The maximum scale factor occurred at a cross-axis angle of $4^{\circ}$. The cosine relationship can be summarized with the equation: $y=\cos \left(\beta+4^{\circ}\right)$ where $y$ is the normalized scale factor ( ${ }^{\circ} /$ Volt).

Figure 1

The $4^{\circ}$ offset is a function of the asymmetrical platinum electrode placement within the electrolytic sensor and will vary slightly from sensor to sensor.

Conclusion: There is a cosine relationship between sensor output and cross-axis inclination. When necessary, this effect can be measured and compensated to improve accuracy.
